Effectiveness and adverse effects of hormonal therapy for prostate cancer: Japanese experience and perspective

Mikio Namiki1, Satoru Ueno1, Yasuhide Kitagawa1, Takashi Fukagai2 and Hideyuki Akaza3

Recently, novel anti-androgens and inhibitors of androgen biosynthesis have been developed through the elucidation of mechanisms of castration resistance of prostate cancer. We believe that these new developments will improve hormonal therapy. On the other hand, there has been an increase in criticism of hormonal therapy, because hormonal therapy is supposed to induce adverse effects such as cardiovascular disease. In this review, we have introduced the Japanese experience of hormonal therapy, because we believe that there may be ethnic differences between Caucasians and Asian people in the efficacy and adverse effects of hormonal therapy. First, we showed that primary hormonal therapy can achieve long-term control of localized prostate cancer in some cases and that quality of life of patients receiving hormonal therapy is rather better than previously thought. Neoadjuvant and adjuvant hormonal therapy in cases undergoing radical prostatectomy or radiotherapy are very useful for high-risk or locally advanced prostate cancer. Further clinical trials are required to confirm the efficacy of neoadjuvant or adjuvant hormonal therapy. We showed that the death from cardiovascular diseases in Japanese patients receiving hormonal therapy was not higher than that in the general population. However, efforts should be made to decrease the adverse effects of hormonal therapy, because life-style change may increase the susceptibility to adverse effects by hormonal therapy even in Japan. Managements of endocrine and metabolic dysfunction, such as diabetes mellitus, are essential. New hormonal compounds such as selective androgen receptor modulators capable of specifically targeting prostate cancer are expected to be developed.

Keywords: adverse effects; androgen deprivation therapy; hormonal therapy; prostate cancer

INTRODUCTION

Hormonal therapy has played an important role in the treatment of prostate cancer, since it was first introduced about 70 years ago by Huggins and Hodges.1 At present, hormonal therapy is still used as the first choice of treatment for advanced prostate cancer. It is frequently used as neoadjuvant or adjuvant therapy in cases undergoing radical prostatectomy or radiotherapy. Furthermore, hormonal therapy is sometimes the primary treatment for localized prostate cancer, especially in aged patients. Although widely used, hormonal therapy has recently been the subject of criticism. Some authors have reported that its effectiveness is minimal,2 while others suggested that it may reduce patients’ quality of life (Qol) and induce adverse effects.3,4 Such reports should be evaluated very carefully. Accurate evaluation of the efficacy of primary hormonal therapy is very difficult, because many factors, such as the type of hormonal therapy used (i.e., castration alone, anti-androgen therapy or combined androgen blockade (CAB)) and the duration of hormonal therapy, affect the outcome of treatment.

In this review, we introduce Japanese experience of hormonal therapy for prostate cancer.

EFFICACY OF PRIMARY HORMONAL THERAPY FOR LOCALIZED OR LOW-RISK PROSTATE CANCER

Hormonal therapy is not recommended as the primary treatment for localized prostate cancer according to representative guidelines, such as the National Comprehensive Cancer Network guidelines. However, according to the Japanese cancer registration statistics, many patients with localized prostate cancer have actually been treated with primary hormonal therapy.5 Despite urologist’s explanation regarding the various treatments for localized prostate cancer, many patients select primary hormonal therapy.6 It is likely that many patients with localized prostate cancer select primary hormonal therapy, because medical treatment, such as primary hormonal therapy, is more acceptable than more invasive treatments, such as surgery, for many Japanese patients. In addition, urologists themselves may also influence patients’ decisions, because they have experience of the effectiveness of primary hormonal therapy.

The ethnic background of patients may play an important role in the effectiveness of hormonal therapy and in susceptibility to adverse effects. The efficacy of hormonal therapy has been compared between Japanese Americans and Caucasians living in Hawaii.7 Both groups had similar backgrounds, but both overall and cause-specific survival rates of Japanese Americans were better than those of Caucasian subjects (Figure 1). The overall survival rate was also compared among Caucasian, Chinese and Filipino patients living in Hawaii. The Chinese subjects showed similar trends to Japanese patients. Therefore, sensitivity of prostate cancer to hormonal therapy and susceptibility to adverse effects may differ among ethnic groups.

Akaza et al. reported that overall survival rate of patients with localized or locally advanced prostate cancer treated with primary hormonal therapy was equivalent to life expectancy of age-matched subjects in the healthy population. Before Akaza’s report, Egawa et al. had already reported that primary hormonal therapy was as effective as radical prostatectomy with regard to disease-specific survival rate in localized prostate cancer. In their report, disease-specific survival rate at 10 years of 56 patients with well-differentiated prostate cancer treated with primary hormonal therapy was 100%. Why is the outcome of primary hormonal therapy so excellent, especially in well-differentiated prostate cancer? Kitagawa et al. analyzed the histological effects of hormonal therapy in specimens from patients treated with radical prostatectomy after neoadjuvant hormonal therapy. They reported that histologically cured or nearly cured patients accounted for more than 40% of the total number. In addition, the recurrence-free survival rate of the patients with histologically complete apoptosis was 100%. These results suggest that some cases of localized prostate cancer could be cured by primary hormonal therapy alone. Schulman et al. also performed neoadjuvant hormonal treatment for 3 months before radical prostatectomy in patients with localized prostate cancer, and reported good histological effects. Labrie et al. also reported that about 80% of stage B prostate cancer could be controlled for long-term with primary hormonal therapy.

These reports raise questions about which groups of patients would be good candidates for primary hormonal therapy. We performed a retrospective review of the efficacy of primary hormonal therapy in 628 patients with localized or locally advanced prostate cancer treated with primary hormonal therapy at seven institutions in Japan, and attempted to predict patients in whom the disease could be controlled for long periods by primary hormonal therapy. Disease-specific survival rates at 8 years in all patients were 89.1% and 75.0%, respectively. In addition, disease-specific survival rate at 8 years of patients given CAB treatment was 95.3%, which was significantly higher than that of patients treated with castration alone. We classified the patients into three risk groups based on pre-treatment prostate-specific antigen (PSA) level and Gleason score according to a modification of the D’Amico risk grouping. Disease-specific survival rates at 8 years of low-, intermediate- and high-risk groups were 97.6%, 95.4% and 78.3%, respectively (Figure 2). Next, we divided low- and intermediate-risk patients into two groups with PSA level <0.2 ng ml⁻¹ after hormonal therapy. The time to PSA level <0.2 ng ml⁻¹ was within 6 months in 192 patients (good response group, group G). These patients accounted for 30.6% of the total patient population. We classified the 139 patients whose PSA level did ≥0.2 ng ml⁻¹ within 6 months as the poor response group (group P). The disease-specific survival rates at 8 years of groups G and P were 98.9% and 94.0%, respectively. Notably, there were no cancer-related deaths during the observation period among the 133 patients in group G receiving CAB treatment in this study. Although a randomized controlled trial may be necessary for utilization of primary hormonal therapy in patients in whom such treatment is considered more effective, based on the results of our study T1c–T3 patients with PSA level ≤20 ng ml⁻¹ and Gleason score ≤7 may be good candidates for the initial hormonal therapy. These patients accounted for 52.7% of the total number of T1c–T3 patients in our study. Hormonal therapy may be suitable as the initial treatment in such patients, but changing to another curative regimen or combination therapy with radiotherapy or radical prostatectomy should be considered, if the PSA value does not decrease to <0.2 ng ml⁻¹ after 6 months of hormonal therapy. However, in patients whose PSA value drops to <0.2 ng ml⁻¹ within 6 months of the commencement of hormonal therapy, continuation of the same regimen may be reasonable with careful observation (Figure 3).

Another preference for early-stage prostate cancer patients involves active surveillance. No study in PSA screened low-risk cancer has ever found that treatment is better than no treatment. Therefore, further investigations are necessary to compare the disease-specific or

that the results for the high-risk group are not necessarily pessimistic in patients whose PSA values drop to <0.2 ng ml\(^{-1}\). They proposed that high-risk prostate cancer patients should be first treated with neoadjuvant CAB. Then, once a PSA value of <0.2 ng ml\(^{-1}\) has been reached, patients with favorable parameters (Gleason score ≤6, pre-treatment PSA ≤20 ng ml\(^{-1}\), time to PSA<0.2 ng ml\(^{-1}\) within 6 months after the commencement of hormonal therapy) are likely to have less possibility (<25%) of relapse at 10 years after commencement of CAB. Therefore, such patients could select any treatment option, e.g., surgery, radiotherapy or primary hormonal therapy. However, they recommended that poor responders to neoadjuvant CAB should be treated with more intensive therapy using CAB combined with high-dose rate brachytherapy, intensity-modulated radiotherapy or some forms of chemotherapy.

**ISSUES OF QOL AND MEDICAL COST**

Long-term hormonal therapy is sometimes criticized for reducing patients’ QoL. In our institution, the QoL of prostate cancer patients treated with primary hormonal therapy was investigated using the Androgen Deficiency in Aging Male questionnaire to allow comparison with healthy aged men who visited the institution for medical examinations. Surprisingly, the QoL of men receiving primary hormonal therapy was rather better than that of the healthy controls, except for sexual function in men aged 50–59 years. Actually, most prostate cancer patients reported no anxiety regarding their primary disease or side effects of the treatment. Kato et al. evaluated health-related QoL in Japanese men receiving hormonal therapy for prostate cancer using SF-36 and University of California at Los Angeles Prostate Cancer Index. They concluded that general health-related QoL was mostly unaffected by hormonal therapy and that most patients did not report sexual bother despite deterioration of sexual function. These reports suggest that QoL of prostatic cancer patients receiving hormonal therapy is rather better than previously thought, at least in Japan.

Medical costs can also be a significant issue. The medical cost of hormonal therapy is higher than those of other treatments, but there are costs that are calculated directly, such as medical costs or transportation for hospital visits, and costs that cannot be calculated, such as loss of employment for disease treatment or psychological burden. Therefore, estimation of cost is very difficult, and further studies are required to compare costs with those of other types of treatment.

**ROLE OF HORMONAL THERAPY FOR HIGH-RISK OR LOCALLY ADVANCED LOCALIZED PROSTATE CANCER**

Patients with high-risk or locally advanced prostate cancer with high Gleason score, elevated PSA level and advanced clinical stage have a high probability of treatment failure after initial management by single-treatment modalities, such as hormonal therapy, radical prostatectomy, external beam radiation therapy (EBRT) or brachytherapy. Therefore, it is extremely important to establish the most effective treatment strategy for patients with high-risk prostate cancer. As high-risk patients may have locally advanced disease with direct extension and/or micrometastases, various combinations of treatments have been developed to augment cancer-specific survival. Neoadjuvant and/or adjuvant hormonal therapy offer synergistic enhancement of radiation therapy or radical prostatectomy due to induction of apoptosis. Moreover, hormonal therapy may play a role in elimination of occult systemic disease. Whereas many studies have demonstrated benefits of hormonal therapy used in conjunction with EBRT to treat locally advanced prostate cancer, questions and criticisms remain, includ-
As the prolonged use of hormonal therapy results in increased incidence rates of adverse events, investigation of the optimal duration of hormonal therapy with maximization of clinical outcome and minimization of toxicity is a logical step in the management of localized high-risk prostate cancer. Further, we determine which patients with high-risk prostate cancer will actually benefit from hormonal therapy, even if there is some compromise in QoL associated with the adverse event profile of this treatment. Trials regarding adjuvant hormonal therapy have already demonstrated the superiority of longer periods of adjuvant hormonal therapy. Therefore, with sufficient care to prevent adverse effects due to hormonal therapy, better outcomes with further longer neoadjuvant hormonal therapy may be achieved. Trimodality treatment (EBRT + brachytherapy + hormonal therapy) has attracted attention as another method to produce better outcomes in cases of high-risk prostate cancer. According to the American Brachytherapy Society, brachytherapy alone is not recommended for high-risk prostate cancer, but can be used as a boost in conjunction with EBRT. In this multimodal approach, combined brachytherapy and EBRT theoretically delivers a possible escalated dose to the prostate and at the same time to extracapsular cancer extension. Although the American Brachytherapy Society provides no clear indications for neoadjuvant and/or adjuvant hormonal therapy with combination of brachytherapy and EBRT in high-risk prostate cancer, the duration of hormonal therapy could be reduced with such multimodality radiotherapy.

In contrast to the many efforts to develop better treatments for radiotherapy with hormonal therapy, there have been few clinical trials investigating the effectiveness of neoadjuvant or adjuvant hormonal therapy with radical prostatectomy. One reason for this is that early studies of neoadjuvant hormonal therapy did not confirm the improvement of overall survival despite improvements in the pathological findings. Another reason is that surgeons may have less interest in medical treatments, such as hormonal therapy. However, surgeons should consider the best methods of improving the results in cases of high-risk prostate cancer, because recent reports have indicated the superiority of radiotherapy for high-risk prostate cancer compared with radical prostatectomy. Recently Dorff et al. reported that 2 years of adjuvant androgen deprivation therapy (ADT) after radical prostatectomy resulted in an extremely low rate of disease recurrence and prostate cancer-specific death for high-risk patients in SWOG S9921 Study.

Finally, it should be stressed that it may be possible to eradicate high-risk or locally advanced prostate cancer with appropriate use of hormonal therapy in combination with radiotherapy or radical prostatectomy. Therefore, further well-designed clinical trials are required.

**ROLE OF HORMONAL THERAPY IN ADVANCED PROSTATE CANCER**

At present, hormonal therapy is still used as the primary treatment for advanced prostate cancer. However, the methods of hormonal therapy, castration alone, anti-androgen agents alone or CAB, are not necessarily the same. This makes the evaluation of hormonal therapy confusing. CAB consisting of ADT with luteinizing hormone–releasing hormone (LH–RH) analog and anti-androgen agents has replaced surgical castration and estrogen agents. In prostate cancer cells, dihydrotestosterone (DHT) is converted from testosterone produced in the testis. DHT which binds with androgen receptor (AR) in the nuclei of prostate cancer cells activates androgen-responsive genes, and finally plays a major role in the proliferation of prostate cancer cells. Androgen deprivation by LH–RH analog or surgical castration induces apoptosis of prostate cancer cells, and the treatment effect for prostate cancer is put out clinically. On the other hand, testosterone and DHT are also converted from dehydroepiandrosterone and androstenedione secreted from the adrenal gland, and it has been reported that approximately 40% of androgen in prostate tissue is derived from the adrenal gland. Moreover, we showed that approximately 25% of testosterone in prostate cancer tissue remained after castration. These results suggested that ADT for prostate cancer requires not only surgical or medical castration using LH–RH analog, but also anti-androgen agents. Anti-androgen agents block the activities of androgens by various mechanisms. Therefore, it is possible that the different clinical outcomes of CAB treatment are due to the various kinds of anti-androgen agents used.

Recently, the results of a phase 3 randomized controlled trial of CAB in advanced prostate cancer showed that LH–RH analog + 80-mg of bicalutamide was more effective than LH–RH analog alone, with favorable safety profiles and cost effectiveness and without deterioration of QoL. Although the effectiveness of CAB treatment has been confirmed, most patients with advanced prostate cancer unfortunately experience relapse, which has been named hormone refractory prostate cancer. To such relapsed prostate cancer after primary ADT failure, chemotherapy using docetaxel could be used as the standard treatment. On the other hand, other modalities of hormonal therapy using other anti-androgen agents, glucocorticoids, estrogens or ketoconazole could be used as the second or third hormonal therapy and have frequently been effective in so-called hormone refractory prostate cancer. Therefore, hormone refractory prostate cancer was shown to be not necessarily hormone-independent, and therefore it has been renamed castration-resistant prostate cancer (CRPC). The mechanisms of CRPC are thought to be as follows. First, these lesions are thought to have higher sensitivity of AR to androgen. AR signaling could be amplified by AR overexpression, AR mutations or changes in AR-interactive factors, such as cofactors. With such higher sensitivity of AR, even low levels androgen can induce AR activation. The second mechanism of CRPC is intraprostatic formation of androgens. As mentioned above, approximately 25%-40% of DHT remains in castrated prostate tissue in which enzymes that convert progesterone to androgen were shown to be overexpressed. This DHT is converted from precursor steroids, which are derived from the adrenal gland and peripheral tissues. This relatively low concentration of DHT may be sufficient to stimulate AR signaling via increased sensitivity of AR.

Given the several mechanisms of action of CRPC, the clinical development of novel agents is still ongoing. MDV3100 is a novel second generation anti-androgen. MDV3100 has greater binding affinity for AR to inhibit DNA binding of androgens to AR. MDV3100 also inhibits nuclear translocation of androgens. In a phase 1/2 multicenter study of 140 patients with CRPC, MDV3100 showed overall >50% PSA decrease in 56% of patients.

Another target in CRPC is inhibition of androgen biosynthesis in prostatic cancer tissues. Inhibition of CYP17 is promising, because upregulation of CYP17 expression has been demonstrated in CRPC tissues. CYP17 catalyzes two essential reactions in androgen biosynthesis, 17β-hydroxylase and C17, 20 lyase. Three novel selective inhibitors of CYP17 are currently under development. As abiraterone...

bolic syndrome in more than 50% of men receiving long-term ADT. Therefore, we should carefully manage patients receiving hormonal therapy, and this is not as difficult as performing complicated surgery. The Endocrine Society Clinical Practice Guidelines will be helpful in preventing cardiovascular disease and DM. Furthermore, we should make our own clinical guidelines for urologists managing prostate cancer patients with hormonal therapy.

ISSUES RELATED TO PATIENT SATISFACTION

The Prostate Cancer Outcome Study yielded interesting results.1 In this study, patients’ satisfaction was compared after each treatment; watchful waiting, primary androgen deprivation, radiotherapy and radical prostatectomy. Satisfaction was higher in men receiving primary ADT than those managed by watchful waiting or radical prostatectomy. In addition, most patients indicated that they would make the same choice, if they had to select the treatment again. Thus, in patients requiring hormonal therapy, criticism of primary ADT should not be simplistic, but rather efforts should focus on decreasing its adverse effects.

CONCLUSION

Hormonal therapy has played an important role in the treatment of prostate cancer, since it was first introduced about 70 years ago by Huggins and Hodges.1 Recently, however, hormonal therapy has been the subject of frequent criticism. Some authors reported that it showed minimal effectiveness, while others suggested that it may reduce patients’ QoL and induce adverse effects. Such reports should be evaluated very carefully.57 From Japanese experiences using hormonal therapy, we suspect that there may be ethnic differences in efficacy and adverse effects of hormonal therapy. Therefore, it is necessary to accumulate further clinical evidence concerning the efficacy and adverse effects of hormonal therapy. We should also strive to decrease its adverse effects, because life-style change may increase the susceptibility to adverse effects by hormonal therapy even in Japan. New hormonal compounds such as selective androgen receptor modulator capable of specifically targeting prostate cancer are expected to be developed.
